## 1. Subproblem

For every  $i \leq C$  and  $j \geq 1$ , we assume that  $\text{opt}(i,j)$  is the smallest total number of moves from lower elevation to higher elevation along the path from  $(1,R)$ . And also, we assume that the elevation of  $\text{square}(i,j)$  is  $e(i,j)$ .

## 2. Base cases

The base case is  $\text{opt}(1,R) = 0$  because we start at  $\text{squar}(1,R)$  and there is no number of move from lower elevation to higher elevation at the first square.

## 3. recursion

To get  $\text{opt}(i,j)$ , we need to move from  $\text{opt}(i-1,j)$  or  $\text{opt}(i,j+1)$  because we only can move immediately below or to the right. And also, if the heights of these squares ( $\text{square}(i-1,j)$  and  $\text{square}(i,j+1)$ ) are greater or equal to the  $\text{square}(i,j)$ , the  $\text{opt}$  value of  $\text{square}(i,j)$  will be the same as those.

So, if we divide the cases, we can say  $\text{opt}(i,j)$  is the minimum value from 1), 2), 3) and 4) which are

- 1)  $\text{opt}(i-1,j)$ , if  $e(i-1,j) \geq e(i,j)$
- 2)  $\text{opt}(i-1,j)+1$ , if  $e(i-1,j) < e(i,j)$
- 3)  $\text{opt}(i,j+1)$ , if  $e(i,j+1) \geq e(i,j)$
- 4)  $\text{opt}(i,j+1)+1$ , if  $e(i,j+1) < e(i,j)$

## 3. How to obtain the final solution

We can get the final solution as getting the last value  $\text{opt}(C,1)$  as we move to  $\text{square}(C,1)$  from the starting point which is  $\text{square}(1,R)$ .

## 4. Time complexity

From the start point which is the base case  $(1,R)$  We need to search all possible values of  $i$  which are between 1 and  $R$ . So, it takes  $O(R)$  time. And also at the same time, for comparing elevations and getting  $\text{opt}$  value, we need to search

all  $j$  values which are between  $C$  and  $1$ . So, It takes  $O(C)$  time. Therefore, the above algorithm runs in time  $O(R) \times O(C) = O(CR)$  .
